Abstract

Laryngeal cancer is a rare cancer, accounts for 12,630 new cases in 2014 out of a total number of 1,665,540 new cancer cases in the United States. It is mostly Squamous in origin as the rest of head and neck tumors. Immunotherapy is an alternative to chemotherapy and radiation therapy to treat cancer. It is utilized to stimulate one’s own immune system to fight the tumor. Giving someone synthetic immune system proteins to fight cancer can also be done in immunotherapy. In this paper, we discuss the pathophysiology of Laryngeal Cancer itself and as part of the squamous cell cancer of head and neck, the active molecules involved in immunotherapy, as well as potential ways to fight these cancers using immunotherapy.

Keywords: Laryngeal Cancer; Head and Neck Cancer; Immunotherapy; Epidermal Growth Factor Receptor; Kinase Inhibitor, Monoclonal Antibody; Cytokine; Vaccine; T Cell; HPV; P53

Abbreviations

HNSCC: Head and Neck Squamous Cell Carcinoma;
HPV: Human Papilloma Virus;
LOH: Loss of Heterozygosity;
Rb: Retinoblastoma;
EGFR: Epidermal Growth Factor Receptor;
mTOR: Mechanistic Target of Rapamycin;
DBD: DNA Binding Domain;
RTK: Receptor Tyrosin Kinase;
CTL: Cytotoxic T Lymphocyte;
Laryngeal cancer is a type of head and neck cancer that arises from squamous cells, the thin, flat cells lining the inside of the larynx. Smoking is the most important risk factor for laryngeal cancer. Death from laryngeal cancer is 20 times more likely for heaviest smokers than for nonsmokers. Heavy chronic consumption of alcohol, is also significant risk factor. When combined with smoking, these two factors appear to have a synergistic effect. People with a history of head and neck cancer especially head and neck squamous cell cancer (HNSCC), are known to be at higher risk (about 25%) of developing a second cancer of the larynx, or lung cancer, additionally the infection with HPV is considered as an independent risk factor. The loss of chromosome region 3p is another genetic modification which occurs in the HNSCC. The most common genetic alteration, the loss of chromosomal region 9p21, is found in 70-80% cases of HNSCC. The CDKN2A gene locus, found on chromosome 9p21, encodes two different types of transcripts. They are p14ARF and p16. These are liable for regulating the G1 phase of the cell cycle and also for the degradation of MDM2 of p53. The p16 is frequently inactivated by homozygous deletion, promoter methylation, or, less commonly, through point mutations.

In laryngeal carcinogenesis dysplasia usually precedes the development of in situ and invasive SCC. Several studies indicate significant overexpression of stable p53 protein in invasive SCC of the larynx and this phenomenon has been associated with heavy smoking closely resembling that observed in lung carcinomas.

It seems that the mutated p53 gene plays a significant role in the early stages of carcinogenesis and may determine progression of the disease during the late stages of tumour development. The most common symptoms of laryngeal cancer are hoarseness of voice, lump in the neck, stridor, sore throat, persistent cough, bad breath and pain when swallowing.

Epidemiology

Laryngeal cancer is relatively rare, with an estimated incidence of 12,630 new cases in 2014 out of a total number of 1,665,540 new cancer cases in the United States. Five year survival rates in the United States are 60%. The larynx is divided into three anatomical regions: the glottis, the supraglottis and the subglottis. Almost all laryngeal malignancies occur in the glottis (2/3) and supraglottis (1/3), with subglottic tumors accounting for only 2%.

Pathophysiology and Molecular Basis of Laryngeal Cancer:

Larynx as its a part of the head and neck shares a common pathophysiology as they are mostly of squamous cell origin, the Head and Neck Squamous Cell Cancer (HNSCC) arises from a common premalignant progenitor followed by the outgrowth of clonal populations. This is associated with cumulative genetic alterations and phenotypic progression to the invasive malignancy. These genetic modifications inactivate tumor suppressor genes and activate proto-oncogenes through gene amplification, point mutations, deletions, and promoter methylation (Table 1). The various microsatellite marker analyses have permitted the description of a genetic progression model for HNSCC. This is based on the regularity of these genetic alterations in the different invasive tumors and pre-invasive lesions. The most common genetic alteration, the loss of chromosomal region 9p21, is found in 70-80% cases of HNSCC. The CDKN2A gene locus, found on chromosome 9p21, encodes two different types of transcripts. They are p14ARF and p16. These are liable for regulating the G1 phase of the cell cycle and also for the degradation of MDM2 of p53. The p16 is frequently inactivated by the homozygous deletion, promoter methylation, or, less commonly, through point mutations.

Table 1. Common molecular abnormalities in HNSCC [18]
Figure 1. HNSCC carcinogenesis hypothetical model [13]

Loss of heterozygosity (LOH) of 17p and the point mutations of the p53 are seen in about 50% of the cases of HNSCC.[12] Around 64% of the p53 mutation take place in G nucleotides in HNSCC, consistent with the exposure to the carcinogens such as tobacco. [24] The overexpression of cyclin D1 and the amplification of 11q13 is found in the 30-60% of the cases of HNSCC. They have also been related with an improved rate of lymph node metastases and overall poor prognosis.[25-27] CyclinD1 induces the phosphorylation of retinoblastoma (Rb), therefore reenabling the progression from G1 to S phase of the cell cycle. It is also found that the phosphorylation of Rb and the progression in the cell cycle from G1 to S phase is increased due to both inactivation of p16 and amplification of cyclin D1. [28]

The gene expression microarrays suggest that a large number of transcriptional alterations take place during the transition from normal mucosa to premalignant lesions, instead of the alteration from premalignant lesion to invasive carcinoma. A study conducted by PK et al. compared normal mucosa with premalignant lesions. The latter expressed 108 upregulated genes and 226 downregulated genes. On the other hand, invasive carcinomas had 5 upregulated genes and 13 downregulated genes when compared with other premalignant lesions. [29]

Epidermal growth factor receptor (EGFR): EGFR is activated through its ligand binding. The EGFR heterodimerizes with different types of receptors in the ErbB family. This dimerization leads to tyrosine kinase activity followed by auto-phosphorylation in its cytoplasmic tail. [30] This function initiates various downstream signaling cascades as well as JAK/STAT, RAS/RAF/MAPK, and PI3K/AKT/mTOR pathways, which are significant regulators of metastasis, invasion, proliferation, and angiogenesis. [31,32]

PI3K/AKT/mTOR: The PI3K activation starts with the phosphorylation of PIP2 (phosphatidylinositols) and successive AKT activation, one of the main effectors of the PI3K signaling pathway. [33] The AKT also activates mTOR, which is responsible for combining various cellular signals such as stress, cellular energy stores, and nutrient levels. The PI3K is also indirectly activated through EGFR when it heterodimerizes with ERBB3. [34]

Pathophysiology based on HPV: The following pathways are involved in the HPV associated head and neck squamous cell cancer:

**TP53:** TP53 is made up of 393 amino acids. It carries 4 domains as well as a highly preserved DNA binding domain (DBD). Inactivation of p53 may be through the deletion of CDKN2A (negatively regulates MDM2). It may also happen through amplification or over-expression of MDM2 (a negative regulator of p53). [35] The p53 inactivation also arises in HPV-positive tumors. The p53-mediated apoptosis does not come out to be the leading form of cell death in the epithelial tumors. [36]

E6 and E7 are the two oncogenes of HPV, which inactivate Rb and p53, respectively. E6 decreases the activity of p53 through binding with E6-AP (UBE3A). It also targets p53 for degradation and ubiquitination. [37]

**Targeted therapy for Laryngeal cancer:**

A. Kinase Inhibitor Drugs:

There are no drugs that are currently approved by FDA for laryngeal cancer. However, few drugs are under clinical trials in phases I, II, and III as in Table 2 below.

1. **Erlotinib:** An aquinazoline derivative with antineoplastic properties. Competing with adenosine triphosphate, erlotinib reversibly binds to the intracellular catalytic domain of epidermal growth factor receptor (EGFR) tyrosine kinase. This reversibly inhibits EGFR phosphorylation and blocks the signal transduction events and tumorigenic effects associated with EGFR activation.

2. **Afatinib:** An orally bioavailable, antineoplastic, anilino-quinazoline derivative and inhibitor of the receptor tyrosine kinase (RTK) epidermal growth factor receptor (ErbB; EGFR) family. Upon administration, afatinib selectively and irreversibly binds to and inhibits the epidermal growth factor receptors 1 (ErbB1; EGFR), 2 (ErbB2; HER2), and 4 (ErbB4; HER4), and certain EGFR mutants. This includes those caused by EGFR exon 19 deletion mutations or exon 21 (L858R) mutations. This may result in the inhibition of tumor growth and angiogenesis in tumor cells overexpressing these RTKs.

Table 2. Non-FDA approved kinase inhibitor drugs[39-40]

Additionally, afatinib inhibits the EGFR T790M gatekeeper mutation, which is resistant to treatment with first-generation EGFR inhibitors. EGFR, HER2 and HER4 are RTKs that belong to the EGFR superfamily; they play major roles in both tumor cell proliferation and tumor vascularization and are overexpressed in many cancer cell types.

**B. Vaccine Therapy:**

There are no vaccines that are currently approved by FDA for laryngeal cancer. However, only vaccine that is under clinical trials in phases I-III is listed in Table 2 below.

1. **MAGE-A3 HPV-16 vaccine:** A multi-epitope "Trojan antigen" (TA) construct vaccine with immune stimulatory and antitumor activities that consists of human melanoma antigen A3 (MAGE-A3) and human papillomavirus (HPV) 16 peptide epitopes linked by the furin-sensitive linker peptide RVKR (arginine-serine-lysine-arginine). The TA construct enters the cytoplasm of antigen-presenting cells (APC) and is processed by the endoplasmic reticulum (ER) and the trans-Golgi network (TGN), where the endopeptidasefurin releases the epitopes from the RVKR linker peptide and, together with various exopeptidases, generates MHC class I-binding peptides. Expressed on the cell surfaces of APC, these MHC class I-binding peptides stimulate a cytotoxic T lymphocyte (CTL) response against tumor cells that display the same peptide epitopes on their cell surfaces.

**C. IDO Inhibitors:**

**Indoleamine-pyrole 2,3-dioxygenase (IDO or INDO EC 1.13.11.52):** is a heme-containing enzyme that in humans is encoded by the IDO1 gene. This enzyme catalyzes the degradation of the essential amino acid L-tryptophan to N-formylkynurenine using the superoxide anion as an oxygen donor [42].

It has been shown that IDO permits tumor cells to escape the immune system by depletion of L-Trp in the microenvironment of cells. A wide range of human cancers such as prostatic, colorectal, pancreatic, cervical, gastric, ovarian, head, lung, etc. overexpress human IDO (hIDO). The details of the study are listed in table 3 below:

**D. PI3k Inhibitors:**

A phosphoinositide 3-kinase inhibitor (PI3K inhibitor) is a class of medical drug that functions by inhibiting one or more of the phosphoinositide 3-kinase enzymes, which are part of the PI3K/AKT/mTOR pathway. Within this pathway there are many components, inhibition of which may result in tumor...

suppression. [44]. The details of the study are listed in table 4 below:

Table 5. PI3K Inhibitors [45]

Conclusion

The recent activities have increased our understanding of the tumor microenvironment, various immunotherapeutic modalities and combination therapies (like chemotherapy with immunotherapy). Additionally, the effects of such modalities in combination with chemotherapy in cancer patients are still in the exploratory phase. The complete perspective of target therapy treatment has not been realized and/or utilized in laryngeal cancer. Proper pre-clinical and clinical designs are the important pillars in understanding the future of immunotherapy in treating cancer patients.
